In Correa's study \[[@B1]\], some improvements in the process of tooth extraction was reported. Generally, tooth extraction in the under-society has been performed by clinical practitioners. However, tooth extraction is not only a dental procedure, but also a surgical procedure. Therefore, tooth extraction is associated with high rates of complications and poor prognosis. The aim of this study was to determine whether or not the process of tooth extraction affects blood pressure or laboratory data, and to determine the prognosis of tooth extraction in the under-society. The data of 128 patients with a mean age of 36.7 years were analyzed retrospectively from 2008 to 2010. Of the patients, 55 were men and 73 were women. All patients had a medical examination before and after tooth extraction. The mean time from tooth extraction to medical examination was 5.1 days. We measured blood pressure (BP), weight, height, triglycerides, total cholesterol, fasting blood sugar and hemoglobin A1c before the extraction and after 1 month. Tooth extraction did not affect laboratory data. The postoperative mean body weight of patients decreased significantly after tooth extraction. The postoperative mean BP of patients increased significantly after tooth extraction. There was no relationship between the change in BP and the treatment modality (semi-extraction, simple extraction, or both extraction and filling). Preoperative co-morbidity is known to have a negative effect on dental treatment. Tooth extraction is associated with the risk of infection, hemorrhage, pain, and hypoxemia \[[@B2],[@B3]\]. However, our results revealed that tooth extraction was not associated with hemoglobin A1c or other laboratory data. The postoperative BP of tooth extraction was higher than that of general population \[[@B4]\]. This finding does not seem to be caused by any risk factors, including preoperative conditions and the treatment modality. The average postoperative weight of patients decreased significantly after tooth extraction. 595f342e71
